ABSTRACT

The purpose of this study is to examine the prevalence of stock picking in UK equities over the period 1991–2005. We describe a metric to analyse trading activity and volumes in the UK FTSE350 and AIM markets, with emphasis on industrial and size-based effects. Our findings indicate that active stock picking has been consistently declining in the UK market over the period studied for all markets, and size quintiles and in virtually every industrial sector. Trading patterns reveal a pronounced size effect in stock picking, and an increase in indexing over time for the AIM but higher overall levels of stock picking relative to the FTSE350 list.

INTRODUCTION

Growth and growth prospects largely underpin firm valuations in efficient markets and in consequence the price at which securities of those firms trade. Investors make financial investment decisions based on their own risk preference, requirements for income over capital appreciation and, critically, on assessments of whether market prices are an accurate reflection of fundamental value. Theories of efficient markets, and standard paradigms of academic and empirical finance have clear implications for asset combination and diversification decisions. If markets are efficient and operate well, prices should reflect all available information regarding firms' financial positions and future prospects and it should not be possible to beat the market other than by chance. The actions of a large number of market participants buying and selling securities based on

firm-specific information should result in a consensus view of professionals regarding fundamental or intrinsic value and a market-clearing price. Investors should only be able to earn abnormal returns by having access to private firm information, superior forecasting ability or through chance. In consequence, rather than incur the significant private costs of research to obtain proprietary information, investors should be as well off investing (passively) in a market index which includes a broad range of different securities. With this approach, the volume of trade in any particular stock should reflect the weight of that firm in the market portfolio/index, and market weighting should explain fully the variation in volume of trade.

However in a climate of low interest rates, as investors seek superior returns one might expect significant active investment as distinct from passive investment. This leads to an upsurge in the use of skill and research on the part of professional investors to identify mispriced securities and trade on that mispricing, a process which is costly and which offers no guarantee that benefits will outweigh the very substantial costs of information acquisition and trading. Strategies designed to identify mispriced shares and to actively beat the market are very expensive. Carhart (1997), amongst others, documents the magnitude of active vis-à-vis passive trading costs and notes that, in terms of net returns, actively managed investment funds have tended to under-perform their passively managed counterparts. If the benefits of active fund management consistently fail to outweigh the costs passive investment is surely more constructive for investors. Malkiel (2003) provides a useful comment on the superiority of active versus passive management of investments, although this debate is not addressed in the present paper.

Despite extensive empirical evidence on patterns in, and costs of, active vis-à-vis passive trading, evidence largely relates to US markets and comparatively little research has been conducted into patterns of trading in UK markets. We consider that an in-depth examination of such patterns for the United Kingdom (UK) is merited at this point and that such evidence would represent an interesting increment to the body of literature in the area, given the significance of the London market globally. While, as noted above, we take no position on the relative merits of active versus passive management of investments, we consider *actual patterns of investment* to be of considerable potential interest to investment speculators seeking to establish the likelihood of mispriced securities in the market. The purpose of this study is to examine the pattern of active versus passive trading in UK equities over the period 1991–2005 inclusive. Drawing on the two fund separation theories (Lo and Wang, 2000; Bhattacharya and Galpin, 2005) we describe a metric to analyse trading activity and volumes in the UK FTSE350 and AIM markets, with emphasis on industrial and size-based effects. The UK is one of the developed markets examined by Bhattacharya and Galpin (2005) but very much in a subsidiary manner. They report a slight (and perverse) increase in stock picking over time for an unspecified UK market index, and leave unexamined the potential of size and industry effects to impact on trading patterns. Focusing centrally on the UK market over the extended period 1991–2005 (relative to Bhattacharya and Galpin (2005)), we conduct monthly regressions of trading

volume on shares outstanding for the FTSE350 (*Financial Times* 350) list, differentiating by market capitalisation (the size effect) and by industry, and including an analysis of the smaller and relatively newer Alternative Investment Market (AIM). Our findings indicate that, rather than reflecting a slight increase as reported by Bhattacharya and Galpin (2005) active stock picking has been consistently declining in the UK market over the period studied for all markets, and size quintiles and in virtually every industrial sector, which evidence is consistent with patterns of trading documented for the United States and some other markets. Moreover our findings imply a significantly lower level of average stock picking for the UK than that reported by Bhattacharya and Galpin (2005). Incrementally, our findings in respect of UK trading patterns reveal a pronounced size effect with significantly less stock picking in larger capitalisation stocks vis-à-vis smaller stocks. Patterns of investment in the AIM suggest an increase in index trading over time but higher overall levels of stock picking relative to the FTSE350 list.

Our paper is structured as follows. The next section presents an analysis of the theoretical motivations for and empirical evidence pertaining to stock and index trading and is followed by section three, which describes our sample and the methodology we apply. The fourth section outlines the results of our analysis together with a discussion of those results and their consistence with the extant literature. In our final section we identify some limitations of our analysis together with some avenues for further study, and conclude.

LITERATURE REVIEW

If the payoffs for identifying mispriced stocks, net of search and trading costs (that is, the benefits of active fund management), are consistently negligible or even negative, passive investment is surely more constructive for investors and one would expect to observe indexing as the dominant investment philosophy if markets truly are efficient.

An interesting research question therefore considers the extent of these two opposing investment philosophies, indexing and stock picking, in the context of the Grossman and Stiglitz (1980) paradox: if everyone believes that markets are efficient and prices fully reflect all available information nobody will stock pick in the hopes of identifying mispriced securities and in consequence markets cannot be efficient, for prices will not move to reflect new price-sensitive information. In essence, efficient markets require sceptical agents. Of course trading costs have an important role to play, as active stock picking is necessarily more expensive than an indexing investment approach, a fact that has been emphasised by the birth and growth of exchange-traded funds (ETFs). ETFs are quoted securities that track a particular index for a fee that is normally just a fraction of a percentage point, and enable investors to hold wide ranges of assets across a variety of asset classes while avoiding expensive fund management costs. It has simply 'never been easier to pay less to invest'. The number of ETFs launched in the first half of 2006 outweighed those launched in 2005 as a whole and this frenetic activity has continued into 2007 (*The Economist*, 2006b: 85). A significant advantage for investors

in the AIM market is the availability of 5 per cent 'taper relief' on gains earned through trading AIM-listed stocks, rising to 10 per cent where stocks are held for four years or more. Such reliefs ultimately act as an incentive for investors to buy and hold stocks rather than actively stock picking in this market, which is of some importance in the context of our present study.

An efficient market is one in which stock prices reflect all available information and wherein investors cannot hope to earn abnormal returns other than through access to proprietary (private) information, superior forecasting ability or by chance. The voluminous literature on market efficiency generally points to markets being at least semi-strong form efficient. Indexing, one of the key concepts of Modern Portfolio Theory, is the practice of investing in a (listed) portfolio containing a large number of stocks and then holding this index for a period of time, the theoretical justification lying in the proposition that markets are efficient, stocks are fairly priced and that the likelihood of poor returns from some stocks in the index will be offset by superior returns in others so that overall portfolio returns are smoothed and not too volatile. Such investment practice emphasises diversification (Markowitz, 1952). Stock picking on the other hand is the philosophical opposite of indexing and focuses on picking winners and losers, those stocks that are mispriced relative to fundamental value and may be expected to generate abnormal returns.

While this paper takes no position on the relative benefits of stock picking vis-à-vis indexing, a number of important points should be made. Strategies designed to identify mispriced shares and to actively beat the market are very expensive. Carhart (1997), amongst others, documents the magnitude of active vis-à-vis passive trading costs and notes that actively managed investment funds have tended to be substantially more costly for investors reducing net investment returns. Jensen (1968) reports that the mean fund in his sample was unable to generate sufficient returns to cover trading costs and would not have out-performed a passive 'buy and hold' investment approach. Gruber (1996) queries why investors choose to buy actively managed funds on finding that active management adds value but that fund charges exceed this value added. Grinblatt and Titman (1989, 1993) report mutual fund out-performance consistent with Wermers' (2000) findings, and their findings with respect to the substantial drag on net returns of actively managed fund transactions costs are consistent with Wermers (2000). A useful comment on the active versus passive debate is provided in Malkiel (2003). In summary the body of literature seems to indicate that active management does not justify the fees typically charged for this service.

To date the main body of literature relating to *the prevalence of* active versus passive investors is not well developed. Such literature as exists regarding persistence in performance, efficient markets and mutual fund performance have been carried out in the United States and typically on US data. Bhattacharya and Galpin (2005) incorporate an important contribution to the debate by developing a metric to measure indexing. These authors collected share volume and shares outstanding data from the Centre for Research in Security Pricing (CRSP) for NYSE, AMEX and NASDAQ listed stocks for the period July 1962–December 2004 and for 43 other markets around the world from DataStream for the period

January 1995–July 2004, in order to conduct cross-sectional monthly regressions. The 43 non-US markets are classified as emerging markets (22) and developed markets (21).

A key finding of Bhattacharya and Galpin (2005) is that there appears to be more stock picking in emerging markets (maximum 63 per cent) vis-à-vis developed markets (maximum 45 per cent), a result which is intuitive given the greater coverage of stocks and sounder institutional arrangements in developed markets. Important exceptions are Germany, which appears to have more stock picking than one would expect for a developed country (maximum 71 per cent) and Russia, which appears to have surprisingly little stock picking (maximum 35 per cent). Notably the maximum proportion of stock picking was lowest in the United States with 29 per cent and greatest in China (maximum 80 per cent). A further key finding is that stock picking appears to be declining systematically around the world, with this decline being most pronounced in emerging markets, although the US data reveal a decline to a low of 24 per cent in the 2000s compared to an average level of stock picking in the late 1960s of 60 per cent. When these authors examine their US data more minutely some further trends and patterns are apparent.

Consistent with the practicalities of indexing, the practice is significantly more extensive for S+P 500 (Standard and Poors 500) vis-à-vis non-S+P 500 stocks, although indexing appears to be gaining in popularity for both categories of shares. Share turnover is also relatively greater for the larger non-S+P 500 shares. At all points examined, indexing seems to be greater for NYSE-listed vis-à-vis AMEX-listed stocks and indexing in the NASDAQ resembled that in the AMEX in the 1980s but more closely resembled trading in the NYSE post-2000, at which time stock picking in NASDAQ-traded stocks started to decline noticeably. There has been a consistent decline in stock picking over time in all three markets however, and an apparent size effect as there seems to be greater indexing in larger stocks across all the US markets examined. Furthermore, partitioning by age, the authors find less stock picking in older stocks vis-à-vis young firm stocks. Again stock-picking is observed to be in decline across firms of all ages and across the ten Fama and French (1996) industry classifications, although the maximum proportion of stock picking is higher in telecommunications, which the authors describe as ‘exciting’ relative to ‘boring’ utilities. Bhattacharya and Galpin (2005) hypothesise that analysts have expertise in identifying mispriced stocks and pick stocks that others should pick later. Using IBES (Institutional Brokers Estimate System) data on analyst following they find, inconsistent with their priors, that investors conduct more stock picking in stocks that analysts do not pick and hypothesise that this seems plausible if by undertaking and acting on their own research analysts consequently reduce the payoff to stock picking on one’s own account. Again stock picking appears to be in decline across both analyst-followed and non-followed stocks with indexing being more pronounced in stocks followed by greater numbers of analysts.

In light of findings that stock picking is declining across all markets and subdivisions of the data studied, Bhattacharya and Galpin (2005, p. 37) question the ‘long-run steady state fraction of stock-pickers’ and develop a model based on

firm-specific risks and payoffs, trading costs and the market price of risk (the market Sharpe ratio) which is then applied to US data for the period 1964–2004. Their findings suggest that firm-specific risk has been increasing over time and that stock picking has declined in tandem. At a long-run estimate of a ‘net benefit to stock picking’ measure, they estimate a steady state maximum proportion of stock picking of approximately 11 per cent, at which level the authors predict that stock picking will eventually settle in the United States.

The UK is one of the developed markets examined by Bhattacharya and Galpin (2005). In terms of world rankings of stock picking, the UK ranks ninth and twenty-first over the periods 1995–99 and 2000–04 respectively with a maximum proportion of stock picking of 47 per cent and 51 per cent respectively. While the estimated differential is not large, it is nevertheless interesting that the UK is one of very few markets in which the extent of indexing actually declined over that period, in consequence of which we consider that a fuller exploration of trading patterns in the UK might yield noteworthy findings. *We also perceive the potential to examine more closely the role of industry, and of firm age or establishment in light of the existence since 1995 of trading in the UK Alternative Investment Market (AIM). It is to this analysis that we now turn.*

DATA AND METHODOLOGY

The main objective of our analysis here is to investigate, illustrate and explain any variation in the patterns of active vis-à-vis passive equity trading over the period 1991–2005 inclusive for the FTSE350 and AIM markets, and specifically to explore any trends in stock picking versus indexing for the period. We seek to ascertain the extent to which trading volume is explained by stock picking in the UK, whether there is a size and/or industry effect in such trading and whether patterns that apply to the FTSE350 main list are also apparent in AIM trading. Our methodological approach is based on that of Bhattacharya and Galpin (2005). Their metric draws on insights from Lo and Wang (2000) who in turn base their theoretical discussion on Tobin’s (1958) two-fund separation theorem.

Briefly, if the two-fund separation theorem holds and everybody in the world indexes between a risk-free asset and a value-weighted proxy for the market portfolio, with no price changes between trades, share turnover for each stock defined as share trading volume scaled by number of shares outstanding, should be identical for all stocks in the portfolio. Essentially (dollar) trading volume in any stock i should be entirely explained by the market capitalisation of that stock. Regressing share trading volume on number of shares outstanding for each stock would yield a beta of 1 and an $R^2 = 1$ if all investment in the market is indexing. To the extent that R^2 differs from 1, there has been a deviation from indexing which could reflect either stock picking or alternative investment strategies such as indexing to an alternative market index, hedging derivative positions, etc. Thus R^2 in the following regression

$$\text{Ln}(VOL)_i = \alpha + \beta_i \text{Ln}(NOSH)_i + \varepsilon_i \quad (1)$$

represents the proportion/extent of indexing in a given market and $(1 - R^2)$ represents the *maximum* proportion of investment trading that can be explained by stock picking. *VOL* is the monthly £ volume of shares traded scaled by market capitalisation, *NOSH* is the £ value of shares outstanding for each stock at the end of that trading month (adjusted for closely held shares). The intercept term α represents the log of turnover and the regression coefficient β describes the relation between trading volume and shares outstanding. The error term may be interpreted as a measure of abnormal volume at the firm level. It is important to note that our stock picking metric represents the *maximum volume of shares traded* that can be explained by stock picking,¹ as it implicitly assumes that investors are indexers or not. The metric does not distinguish between stock picking and the activities of hedge funds and funds of funds for example. However we consider that its appeal lies in its simplicity, understandability and ease of computation, requiring neither a highly quantitative background nor appreciation of complex statistics for its comprehension. It yields a measure that by default describes the extent of indexing in the market and in consequence allows us to infer trends in approaches to investment over the period studied.

Our analysis of the nature of stock trading activity in the UK centres on the FTSE350 list which we consider offers a happy medium between the small number of stocks that constitute the FT100 main list and the larger FTALLSH index which would present considerable data challenges. For comparative purposes we also analyse trading patterns for the newer AIM market, which commenced trading in June 1995 and which offers smaller firms an opportunity to access capital without the rigorous listing requirements of a full listing. Companies that list and enjoy share trading on the AIM are typically smaller and younger than those on the main list. For each month over the period January 1991–December 2005 we obtain (aggregate) trading volume and *NOSH* data (at month end) for every firm in our sample and conduct monthly regressions as in equation (1) above. To be included in our sample a share must be an ordinary common share and be listed in its own country. There was some variation in the constituents of the FTSE350 list, some companies disappearing over time and others not having obtained a listing until after the sample period commenced. We select at random 210 companies on which to base our analysis, representing 60 per cent of the constituent firms at any point in time. These data were obtained from DataStream.

For our size analysis we partition our sample companies into quintiles according to market capitalisation for every month, quintile 1 (5) containing the largest (smallest) stocks by market value respectively and we conduct difference of means tests on $(1 - R^2)$ measures to assess any size effect. For our industry analysis we base our analysis on the DataStream industry classifications, which has 25 groupings. Some categories had fewer than four companies so we reclassified these firms under the ‘other’ classification, resulting in 17 distinct groupings for the FTSE350 sample. Codes ranging from 1 to 17 inclusive were accorded to each firm to facilitate our differentiation by industry. We do not seek to explore the existence of a size or industry effect in our AIM sample for which just ten years of data were available: January 1996–December 2005.² Our metrics of key interest are R^2 and by extension $(1 - R^2)$ which represent the proportion of indexing (maximum

proportion of stock picking) respectively, though the intercept term, which represents log of turnover, also provides some useful hints about the absolute volume of trade in the various data sets. We conduct the Ryan-Joiner test of normality and the Durbin-Watson test for autocorrelation and find no non-stationarity in our data. Skewness is predictably a feature as turnover is necessarily bounded by 0, which induces positive skewness. We employ the White test for heteroskedasticity, again this is not a feature of our data though it might plausibly have been present in such time-series data. In consequence we utilise OLS (ordinary least squares) and base our tests of significance on parametric P-values and (Fischer) F-statistics, and our t-statistics are of the 2-sided test of the null $\beta = 1$.

As the error term in our cross-sectional regression represents a measure of abnormal volume at the firm level, we obtain monthly returns for each firm over the sample period from DataStream and relate them to this abnormal volume measure as follows:

$$R_{it} = \alpha + \beta(AVol)_{it} + \varepsilon_i \tag{2}$$

where R_{it} is the firm-level return for firm i in month t , $AVol_{it}$ is abnormal volume from equation (1), α and β are regression coefficients and ε_i the error term, to explore whether abnormal volume might have explanatory or predictive power for returns. Table 1 describes our data for both FTSE350 and AIM companies at 31 December 2005, the end point of our sample period.

TABLE 1: DESCRIPTIVE STATISTICS

Market	FTSE350		AIM	
Number of Companies	210		500	
Mean MV £m	6,778.5		31.3	
Mean Volume 000s	150.75		3.69	
Mean NOSH 000s	1205.55		155.76	
Variables	Ln(VO)	Ln(NOSH)	Ln(VO)	Ln(NOSH)
No. of observations	37800	37800	59760	59760
Mean	10.251	12.814	5.762	10.451
Median	10.246	12.777	5.929	10.360
SE (Mean)	0.009	0.007	0.01	0.007
Std. Deviation	1.605	1.264	2.539	1.53
Minimum	1.569	8.509	2.302	2.303
Maximum	16.56	18.04	14.17	17.52
Skewness	-0.02	0.26	-0.31	0.01
Kurtosis	2.96	3.09	2.88	3.17
Durbin-Watson	1.87	1.91	1.89	1.88
Ryan-Joiner	0.999	0.997	0.997	0.996

MV=Market Capitalisation; Volume=aggregate volume of shares traded per month; NOSH=number of shares outstanding at end of calendar month; statistics presented are averages across all shares in each list respectively at 31 December 2005.

Clearly and unsurprisingly the mean FTSE350 firm is larger, enjoys significantly greater aggregate monthly trading volume and has significantly greater numbers of shares outstanding than its AIM counterpart. There is no minimum market capitalisation requirement for an AIM listing and the FTSE350 market has substantially greater market liquidity.

RESULTS

Table 2 presents the results of applying equation (1) above to our FTSE350 data, where R^2 ($1 - R^2$) represent the proportions of indexing (maximum stock picking) respectively. Our sample period pre(post)-dates that of Bhattacharya and Galpin (2005) by some four (one) years. We are unclear about the specific stocks that constitute their UK list so that comparisons are somewhat problematic other than in general import and theme.

Our beta value is greater than 1 at the 1 per cent level throughout so that while volume was approximately linear in NOSH an increase in shares outstanding resulted in a greater percentage change in the volume of trading with this effect being more pronounced through time. Our F-statistics suggest that the regression is highly significant in every period studied. R^2 , the measure of proportionate indexing, shows a clear trend upwards and there is a corresponding decline in the extent of stock picking and other non-indexing trades, which accords both with our priors and with evidence for the United States and other markets documented

TABLE 2: (MAXIMUM PROPORTION OF) STOCK PICKING IN THE FTSE350

Year	R^2	$(1 - R^2)$	F-stat	Beta	P-value
1991–2005	69.1	30.9	505.89	1.09	0.000
1991	53.9	46.1	158.62	1.01	0.000
1992	52.7	47.3	165.05	1.03	0.000
1993	60.1	39.9	234.9	1.02	0.000
1994	61.4	38.6	256.18	1.02	0.000
1995	59.1	40.9	236.67	1.03	0.000
1996	64.2	35.8	298.55	1.06	0.000
1997	67.4	32.6	372.81	1.08	0.000
1998	67.0	33.0	393.4	1.06	0.000
1999	72.5	27.5	525.17	1.11	0.000
2000	78.3	21.7	737.91	1.12	0.000
2001	78.3	21.7	764.16	1.16	0.000
2002	82.0	18.3	953.14	1.19	0.000
2003	81.1	18.9	895.42	1.19	0.000
2004	79.2	20.8	789.05	1.16	0.000
2005	79.5	20.5	807.28	1.12	0.000

Model: $\ln(VOL)_i = \alpha + \beta_i \ln(NOSH)_i + \varepsilon_i$

Vol = £ volume of shares traded; NOSH = number of shares outstanding; measures are mean annual results based on monthly regressions described by the model.

by Bhattacharya and Galpin (2005). Our mean (maximum proportion of) stock picking at 31 per cent appears lower than the median reported by Bhattacharya and Galpin (2005) of 49 per cent. We report a systematic decline in stock picking over time while Bhattacharya and Galpin (2005) report a slight increase in stock picking for the later years in their sample (to 51 per cent for the 2000–04 period).

Our difference of means tests indicate that the level of indexing was significantly lower in 1991 relative to both the average over 1991–2005 (t-stat 21.62, p-value 0.000) and to the level recorded for 2005 at the end of our sample period (t-stat 24.61, p-value 0.000). These findings are consistent with those of Bhattacharya and Galpin (2005), who document a decline from 60 per cent to 24 per cent over the period 1960s–2000s for US markets. Figure 1 highlights this pronounced decline in stock picking over time for the FTSE350.

Table 3 presents the findings of our size analysis for quintiles of the FTSE350 where quintile 1 (5) represents the largest (smallest) stocks by market capitalisation respectively and metrics are mean values for the 1991–2005 period. For all quintiles the model statistics indicate significance at the 1 per cent level and there is a clear size effect evident in the data with indexing being significantly greater in larger stocks vis-à-vis smaller ones. Difference of means tests confirm this size effect, (t-stat 22.05, p-value 0.000), and also that within each quintile there has been a systematic and significant decline in stock picking over time, a pattern that is evident in Figure 2.

These findings are consistent with Bhattacharya and Galpin (2005), who document a similar size effect and time trend for US stocks. We are unsurprised with

these data; stock picking tends to be more prevalent in markets where there is less public disclosure of stock-specific information, and analyst following (and consequent publication of price-sensitive information) is greater for larger capitalisation stocks. For our industry analysis we partition our FTSE350 stocks into the DataStream classifications as discussed in Section Three above. The mean number of companies per industry was 12.35 with a maximum of 19 and minimum of four respectively. Table 4 presents our findings with respect to these groupings for the period 1991–2005.

TABLE 4: (MAXIMUM PROPORTION OF) STOCK PICKING IN THE FTSE350 BY INDUSTRY

Industry	R ²	(1 – R ²)	Beta	F-stat	P-value	Rank

Model: $\ln(VOL)_i = \alpha + \beta_i \ln(NOSH)_i + \varepsilon_i$

Vol = £ volume of shares traded; NOSH = number of shares outstanding; measures are mean annual results based on monthly regressions described by the model. Other* classification includes 40 companies from the following industries; auto and parts, beverages, tobacco, Personnel, H/C and Services, Mining, Construction, for which there were fewer than 4 firm-industry observations.

There is considerable variation in the relative dominance of each investment philosophy across industry type with stock picking in the electrical and utility industries being significantly greater than the mean and the chemical and pharmaceutical industries being significantly less. While not reported here, our $(1 - R^2)$ measures indicate a systematic decline in stock picking over the period studied for every industrial grouping. To an extent our findings are consistent with those of Bhattacharya and Galpin (2005) who report greater indexing in the 'boring' utility sector, as do we, however we find no 'exciting' telecoms effect, stock picking in this UK sector having fallen over time rather than the reverse, which appears to have been the US experience.

If analysts improve the information environment of the stocks they research and pick, thus reducing the benefits of stock picking, it seems intuitive that the returns to information gathering and in consequence stock picking will be greater in stocks that have less analyst following. The UK stocks in the FTSE350 have widespread following but this is much less the case in AIM-listed stocks, which tend to be smaller, younger start-up enterprises without the trading history or visibility of larger stocks. Table 5 reports our indexing (non-indexing) metrics for AIM-listed stocks for the period 1996–2005 inclusive, the AIM having commenced trading only in June 1995.

**TABLE 5: (MAXIMUM PROPORTION OF) STOCK PICKING
IN THE AIM 1996–2005**

Period	R ²	(1 – R ²)	F-stat	Beta	P-value
1996–2005	23.0	77.0	164.80	0.754	0.000
1996	1.6	98.4	10.79	0.192	0.591
1997	24.6	75.5	38.85	0.788	0.000
1998	20.3	79.7	47.96	0.73	0.000
1999	24.2	75.8	79.74	0.851	0.000
2000	16.0	84.0	76.31	0.626	0.050

2002	17.0	83.0	87.99	0.716	0.000
2003	25.0	75.0	135.32	0.851	0.000
2004	39.1	60.9	233.48	1.043	0.000
2005	45.8	54.2	292.25	1.156	0.000

Model: $\ln(VOL)_i = \alpha + \beta_i \ln(NOSH)_i + \varepsilon_i$

Vol = £ volume of shares traded; NOSH = number of shares outstanding; measures are mean annual results based on monthly regressions described by the model.

In 1996, the first full year of trading in AIM-listed stocks, thin trading would likely be a feature of the exchange and the concept of indexing substantially premature – formal indexing essentially became possible only from January 1999 when approximately 320 firms were listed, though AIM firm numbers were 500 from 2001. For the period as a whole mean indexing is increasing, although 2000 saw somewhat of a resurgence of the stock picking practice, which effect is likely due to the popularity of high technology and start-up stocks at the time, a large number of which would have been listed on the AIM. Only towards the end of our sample period does volume traded approach linearity with shares outstanding, in the earlier years of the exchange's existence volume traded fell substantially short of outstanding shares. When we compare indexing (non-indexing) in the FTSE350 with the AIM (for the period 1996–2005) our difference of means tests indicate that indexing was significantly greater (lower) in the FTSE350 (AIM) stocks overall and in each calendar year, and our intercepts suggest greater turnover in FTSE350 shares but more trading in larger AIM stocks vis-à-vis smaller ones.

At the end of our sample period indexing in the FTSE350 averaged 79.5 per cent compared with 45.8 per cent for the AIM. From a practical perspective (and indexing is the practical manifestation or implementation of the tenets of modern portfolio theory) indexing is of course far easier for the FTSE350 stocks and would not have been possible before 1999 for the AIM. However both groups indicate a systematic trend upwards in indexing at the expense of stock picking, which is more pronounced in the AIM, possibly because stock picking started at a substantially greater level, also because the decline in stock picking for the FTSE350, for which we have a longer time series of data, pre-dates this comparative period. It remains to be seen whether levels of stock picking for these exchanges will converge over time or whether there is always likely to be somewhat less indexing in the AIM vis-à-vis the FTSE350, which pattern has been observed for the NASDAQ

FIGURE 3: (MAXIMUM PROPORTION OF) STOCK-PICKING IN THE FTSE350 AND AIM FOR THE PERIOD 1996–2005 INCLUSIVE

relative to the NYSE for the US market. There are substantial tax breaks available to investors who buy and hold AIM-listed stocks, which provide a disincentive to more active trading in individual shares. Figure 3 depicts these trading patterns for UK markets for the period 1996–2005.

In summary, we report here a significant decline in stock-picking for both FTSE350 and AIM markets over time, which results are robust to size and industry sector, and in general small capitalisation stocks are shown to attract greater stock picking activity than larger capitalisation stocks. While we do not undertake any systematic analysis of an abnormal trading volume association with firm returns, we identify this area as potentially yielding interesting research findings moving forward.

CONCLUSION

In efficient markets asset prices fully reflect all available firm-specific information and it should not be possible to beat the market other than by chance. If asset prices do not reflect all relevant information, it may be possible to earn superior returns by undertaking research to identify value-relevant firm information and taking action thereon. The purpose of this study was to examine the pattern of active versus passive trading in UK equities over the period 1991–2005 inclusive. Our metric to analyse trading activity and volumes on the UK FTSE350 and AIM markets draws on the two fund separation theories

(Lo and Wang, 2000; Bhattacharya and Galpin, 2005), and we explore industrial and size-based effects.

Our findings indicate that active stock picking has been consistently declining in the UK market over the period studied for all markets, size quintiles and in virtually every industrial sector, although the AIM did see a brief resurgence of stock picking around 2000-01 at the height of the dot.com investment bubble. Moreover, trading patterns in the larger capitalisation FTSE350 list reveal a pronounced size effect with significantly less stock picking in larger capitalisation stocks vis-à-vis smaller stocks. Patterns of investment in the AIM suggest an increase in index trading over time but higher overall levels of stock picking relative to the FTSE350. This is likely due to the shorter history of the AIM and the characteristics of stocks traded thereon; however it will be interesting to observe whether trading patterns converge with those of the FTSE350, as has been observed for the NASDAQ vis-à-vis the NYSE markets, when we have a longer time series of data for the AIM. Our results are not especially surprising and are largely consistent with those of Bhattacharya and Galpin (2005), although we do report a level of stock picking for our FTSE350 that is substantially less than that which Bhattacharya and Galpin (2005) report for their undefined UK market. If our constituent stocks are on average larger than theirs, taken in conjunction with our pronounced size effect there may be a resolution of the differential here.

We fail to find any well-defined 'excitement/boredom' factor in patterns of industrial trading, though we report the greatest relative extent of indexing in the chemical and pharmaceutical sector, which is characterised in the UK by relatively small numbers of large capitalisation stocks.

The evolution of the estimated stock picking impact over time is an issue that merits some consideration. The period covered by our study spans several cycles in the market from recession through recovery and expansion and back to recession from which a further recovery eventually materialised in the early years of this century. Over the period, many economic and geo-political events occurred which may well have influenced investor behaviour for which our statistics proxy. Throughout that period there has been a pronounced and consistent decline in active stock picking at the expense of passive investment, and we remind ourselves that our stock picking metric includes all non-indexing behaviour. Essentially and notwithstanding developments such as the introduction of ETFs and the increasing activity of hedge funds, active investment appears to be in decline. Whether this decline continues or whether stock picking will eventually settle at some 'long-run steady state level' remains to be seen. Was this level, if it emerges, to be significantly lower than the mean level we report at the end of our sample, such a development would have serious implications for financial activity in the City and for a fund management industry which has exhibited unprecedented growth in the past decade.

We recognise the simplistic nature of the Bhattacharya and Galpin (2005) metric we compute in respect of stock picking in that it essentially measures all 'non-indexing' investment behaviour. An interesting avenue for further study involves a more granular exploration of the impact, if any, of exchange traded funds on investors' decision choices and whether this relatively low-cost investment

approach, which amplifies the net returns differential between indexing vis-à-vis active investment, has substantially hastened the observed decline in stock picking. These are themes that we hope to pursue in the future.

NOTES

- ¹ R^2 will differ from 1 if agents either pick individual stocks in which to invest or alternatively index to tailored portfolios such as hedge funds of funds or exchange-traded funds, which latter have enjoyed increasing popularity in recent times.
- ² We omit the period 1 June 1995–31 December 1995 to allow for market settling in this introductory trading period.
